Abstract
Two constituents of bile, bilirubin and taouroursodeoxycholic acid (TUDCA), have antioxidant activity. However, bilirubin can also cause damage to some neurons and glial cells, particularly immature neurons. In this study, we tested the effects of bilirubin and TUDCA in two models in which oxidative stress contributes to photoreceptor cell death, prolonged light exposure and rd10+/+ mice. In albino BALB/c mice, intraperitoneal injection of 5 mg/kg of bilirubin or 500 mg/kg of TUDCA prior to exposure to 5000 lux of white light for 8 h significantly reduced loss of rod and cone function assessed by electroretinograms. Both treatments also reduced light-induced accumulation of superoxide radicals in the outer retina, rod cell death assessed by outer nuclear layer thickness, and disruption of cone inner and outer segments. In rd10+/+ mice, intraperitoneal injections of 5 or 50 mg/kg of bilirubin or 500 mg/kg of TUDCA every 3 days starting at postnatal day (P) 6, caused significant preservation of cone cell number and cone function at P50. Rods were not protected at P50, but both bilirubin and TUDCA provided modest preservation of outer nuclear layer thickness and rod function at P30. These data suggest that correlation of serum bilirubin levels with rate of vision loss in patients with retinitis pigmentosa could provide a useful strategy to test the hypothesis that cones die from oxidative damage in patients with retinitis pigmentosa. If proof-of-concept is established, manipulation of bilirubin levels and administration of TUDCA could be tested in interventional trials.

Keywords: antioxidants, oxidative damage, reactive oxygen species, retinal dystrophies, retinal photoreceptors, retinitis pigmentosa.

Retinitis pigmentosa (RP) is a group of diseases in which a mutation leads to rod cell death. Hundreds of different mutations that lead to RP have been identified. The mechanism of rod cell death is likely to vary depending upon the mutation. Some mutations in genes that are differentially expressed in rod photoreceptors cause protein misfolding and endoplasmic reticulum stress leading to rod cell death (Hwa et al. 1999; Illing et al. 2002; Aherne et al. 2004; Tam and Moritz 2006). Other proposed mechanisms include continuous activation of phototransduction, abnormal cellular transport, or instability of inner or outer segments because of dysfunction of structural proteins (Liu et al. 2003; Chen et al. 2006; Krebs et al. 2010). As the regeneration of rhodopsin depends upon the retinoid cycle through which all-trans retinal is converted back to 11-cis-retinal which binds with opsin, dysfunctions in phototransduction can result in abnormalities in the retinoid cycle and vice versa. Disruption of the retinoid cycle causes elevated levels of highly reactive retinoids, such as all-trans retinal, which are toxic. In fact, excessive and/or prolonged light stimulation in normal animals leads to photoreceptor degeneration from accumulation of all-trans retinal (Maeda et al. 2009). The heterogeneity in the mechanism of rod cell death in RP suggests that any one particular treatment is likely to apply only to a small subgroup of patients that share the same mechanism.

However, it is not the death of rods that is debilitating in patients with RP, but rather the death of cones that inevitably
follows rod cell death. Loss of rods decreases function in dim illumination but not normal illumination, whereas loss of cones leads to constriction of the visual fields and eventual blindness. Rods make up the majority of cells in the outer retina, roughly 98% in mice and 92% in humans, but the percentage varies considerably based upon the position within the retina (Curcio et al. 1993). Rods are metabolically active cells that consume the vast majority of oxygen delivered to the outer retina. After rods die, oxygen delivery is unchanged, but oxygen consumption is greatly reduced resulting in a large increase in oxygen in the outer retina (Yu et al. 2000). The increase in oxygen results in generation of reactive oxygen species (ROS) from stimulation of NADPH oxidase and probably also from run off from the electron transport chain, resulting in progressive oxidative damage and death of cones (Shen et al. 2005; Komeima et al. 2006; Usui et al. 2009a). Oxidative damage contributes to cone cell death in several models of RP with different underlying pathogenic mutations (Komeima et al. 2007) and thus may be applicable in all patients with RP. Thus, development of new treatments that effectively protect photoreceptors from oxidative stress is a high priority. Such treatments may also provide benefit in patients with age-related macular degeneration, because antioxidant vitamins reduce the risk of progression from intermediate to advanced forms of the disease (Age-Related Eye Disease Study Research Group 2001).

An appealing therapeutic strategy is to utilize components of the endogenous antioxidant defense system as they are likely to be well-tolerated. Each tissue contains a group of enzymes that detoxify reactive oxygen species, but it is difficult to utilize enzymes as therapeutic agents. Some small molecules that seem to play other roles in the body may also be components of the antioxidant defense system. Bilirubin, the end product of heme metabolism and uric acid, the end product of purine metabolism, have antioxidant activity (Stocker et al. 1987a,b). The evidence that bilirubin has a physiological function as an antioxidant is particularly strong. Elevated plasma bilirubin levels provide protection in a number of disease processes in which oxidative stress has been implicated (Ishizaka et al. 2001; Vitek et al. 2002; Djousse et al. 2003; Novotny and Vitek 2003). Local production of bilirubin through heme oxygenase (HO) 1 or HO2 and biliverdin reductase also provides protection against oxidative stress in some tissues (Llesuy and Tomaro 1994). In some neuronal populations, HO2 is particularly important, because mice deficient in HO2 show increased ischemia-induced damage in some brain regions (Dore et al. 1999a,b, 2000). Lipophilic bilirubin demonstrates greater antioxidant activity for lipids than the endogenous glutathione pathway, which preferentially protects proteins (Sedlak 2009).

Like bilirubin, other constituents of bile, the bile acids, can either be damaging or protective to cells. Most bile acids are hydrophobic, very insoluble, and in high concentrations cause damage to cell membranes. Obstruction of bile ducts or liver diseases can result in elevated levels of bile acids, cholestasis, which is damaging to the liver. Ursodeoxycholic acid (UDCA), a minor (4%) constituent of bile, is hydrophilic unlike other bile salts and when given as an oral supplement, reduces liver damage in the setting of cholestasis; it has been approved by the Federal Drug Administration for patients with primary biliary cirrhosis (Lazaridis et al. 2001). While the exact mechanism of its protective effect for liver cells is not known, it has been demonstrated that UDCA reduces apoptosis induced by hydrophobic bile salts, possibly by membrane stabilization and/or reducing mitochondrial damage (Heuman and Bajaj 1994; Botla et al. 1995; Rodrigues et al. 1998). Also, both UDCA and its taurine-conjugated analog, TUDCA, have cytoprotective effects in a number of animal models including models of retinal degeneration (Boartright et al. 2006; Phillips et al. 2008). In this study, we investigated the effects of bilirubin and TUDCA on photoreceptor survival and function in a model of excessive light exposure and a model of RP.

**Materials and methods**

**Treatment with bilirubin IX-α or TUDCA**

Mice were treated in accordance with the recommendations of the Association for Research in Vision and Ophthalmology. In these experiments, bilirubin IX-α was bound to human serum albumin (HSA) prior to administration, because HSA is the physiologic carrier for bilirubin and free bilirubin is not available to peripheral tissues. Bilirubin IX-α was dissolved in 50 mM NaOH in distilled water and incubated with HSA in a mass ratio of 1:140 to obtain bilirubin bound to HSA. Litters of homozygous rd10+/+ transgenic mice or BALB/c mice were given subcutaneous injections of bilirubin (5 mg/kg)/HSA (700 mg/kg) or TUDCA (500 mg/kg) dissolved in 0.15 M NaHCO3. The control group for bilirubin-treated mice was given injections of 700 mg/kg of HSA and the control group for TUDCA-treated mice was given 0.15 M NaHCO3.

**Light-induced retinal degeneration model**

One day and again 1 h prior to light exposure (5000 lux for 8 h), 4- to 6-week-old female albino BALB/c mice were given an injection of bilirubin, HSA, TUDCA, or NaHCO3. Female mice were used for these experiments because they are less aggressive resulting in fewer injuries from fighting, but there is no scientific reason to exclude males. Solutions were prepared immediately prior to injections and pH was adjusted to 7.4. After 8 h of light exposure, mice were dark adapted for 18 h and then scotopic and photopic electroretinograms (ERGs) were performed (Day 1 ERGs). Mice were then housed under normal cyclic lighting conditions (light 12 h/dark 12 h). On day 7, scotopic and photopic ERGs were repeated and mice were killed to measure outer nuclear layer (ONL) thickness or cone density. Some mice received an injection of hydroethidine prior to death to assess superoxide radicals in the retina.
Rd10 model of retinal degeneration

Rd10+/+ mice were purchased from Jackson Labs (Bar Harbor, ME, USA) and were maintained on a C57BL/6 background. Starting at postnatal day (P) 6, both males and females were given subcutaneous injections of 5 mg/kg of bilirubin, 500 mg/kg of TUDCA, or their respective control injections every 3 days. At P30, scotopic and photopic ERGs were done and some mice were killed to measure ONL thickness. At P50, ERGs were done and mice were killed to measure ONL thickness or cone density.

Assessment of superoxide radicals with hydroethidine

The in situ production of superoxide radicals was evaluated using hydroethidine as previously described (Komeima et al. 2008). Superoxide radicals convert hydroethidine to ethidium, which binds DNA and emits red fluorescence at approximately 600 nm. Briefly, two intraperitoneal (i.p.) injections of 20 mg/kg of hydroethidine (Invitrogen, Carlsbad, CA, USA) were administered 30 min apart and mice were kept in the dark for 18 h and then killed. Eyes were removed and 10 mm frozen sections were fixed in 4% paraformaldehyde for 20 min at 23°C, rinsed with phosphate-buffered saline (PBS), and counter-stained for 5 min at 23°C with the nuclear dye Hoechst 33258 (1 : 10 000; Sigma, St. Louis, MO, USA). Slides were rinsed in PBS, and then examined by fluorescence microscopy (excitation: 543 nm, emission > 590 nm) with a Zeiss LSM 510 META confocal microscope using a Zeiss Plan-Apochromat 20×/0.75NA objective lens (Carl Zeiss, Oberkochen, Germany). All images were acquired in the frame scan mode with the same exposure time. The excitation wavelength was set at 405 nm for visualization of Hoechst.

Measurement of cone cell density

Cone density was measured as previously described (Komeima et al. 2006; Usui et al. 2009b). Briefly, each mouse was killed, and eyes were removed and fixed in 4% paraformaldehyde overnight at 4°C. After washing with PBS, the cornea, iris, and lens were removed. A small cut was made at 12:00 h for orientation and after four radial cuts, equidistant around the circumference, the entire retina was carefully dissected from the eye cup and any adherent retinal pigmented epithelium was removed. Retinas were placed in PBS containing 1% Tween 20 (Promega Corporation, Madison, WI, USA) for 30 min at 23°C, incubated for 1 h at 23°C in 1 : 200 rhodamine-conjugated peanut agglutinin (Vector Laboratories, Burlingame, CA, USA) in PBS containing 1% Tween 20. The retinas were rinsed three times for 10 min in PBS containing 1% Tween 20, given a final rinse in PBS and flat-mounted. The retinas were examined with a Zeiss LSM 510 META confocal microscope with a Zeiss Plan-Apochromat 20×/0.75NA objective lens for high magnification using an excitation wavelength of 543 nm to detect rhodamine fluorescence. Images were acquired in the frame scan mode. Cone cells were counted using high magnification images within four 0.0529 mm² bins located 1.0 mm superior, inferior, temporal, and nasal from the center of the optic nerve. The investigator was masked with respect to experimental group.

Measurement of ONL thickness

Rd10+/+ mice were randomized to treatment with bilirubin, TUDCA, or their respective controls (HSA or NaHCO₃) every 3 days starting at P6. At P30 or P50, mice were killed, eyes were removed, the 12:00 position was marked, and 10 mm frozen serial sections were cut parallel to the 12:00 to 6:00 meridian through the optic nerve and stained with hematoxylin and eosin. The thickness of the ONL was measured by image analysis at three locations (I1, I2, and I3) between the inferior border of the retina at 6:00 and the optic nerve and at three locations (S1, S2, and S3) between the superior border of the retina at 12:00 as previously described (Komeima et al. 2007).

Recording of ERGs

An Espion ERG Diagnosys machine (Diagnosys LLC, Littleton, MA, USA) was used to record ERGs as previously described (Okoye et al. 2003; Komeima et al. 2006, 2007; Ueno et al. 2008; Usui et al. 2009b). The mice were anesthetized with an i.p. injection of ketamine hydrochloride (100 mg/kg) and xylazine hydrochloride (Santen Pharmaceutical Co., Osaka, Japan). The mice were placed on a pad heated to 39°C, and platinum loop electrodes were placed on each cornea after application of Gonioscopic prism solution (Alcon Labs, Fort Worth, TX, USA). A reference electrode was placed subcutaneously in the anterior scalp between the eyes and a ground electrode was inserted into the tail. The head of the mouse was held in a standardized position in a Ganzfeld bowl illuminator that ensured equal illumination of the eyes. Recordings for both eyes were made simultaneously with electrical impedance balanced. Low background photopic ERGs were recorded at 1.48 log (cd/m²) under a background of 10 cd/m². Sixty photopic measurements were taken and the average value was recorded.

Statistical analysis

Statistical comparisons were done using unpaired Student’s t-test or two-way analysis of variance (ANOVA) with Bonferroni correction for multiple comparisons.

Results

BALB/c mice treated with bilirubin or TUDCA showed significant resistance to light toxicity

Exposure of albino BALB/c mice to intense light for 8 h causes photoreceptor degeneration because of oxidative damage (Noell and Albrecht 1971; Li et al. 1985; Tanito et al. 2002). One day after light exposure, there was a marked reduction in rod photoreceptor function measured by scotopic a- and b-wave amplitudes and cone photoreceptor function measured by photopic b-wave amplitudes in untreated BALB/c mice (Fig. 1). Compared to mice treated with the respective vehicles (HSA or NaHCO₃), mice treated with 5 mg/kg of bilirubin or 500 mg/kg of TUDCA had significantly greater mean scotopic a- and b-wave amplitudes, and photopic b-wave amplitudes. The reduction in retinal function was even greater 7 days after light exposure and was partially prevented by treatment with bilirubin or TUDCA.
Fig. 1 Bilirubin and TUDCA reduce loss of retinal function because of constant light exposure in BALB/c mice. BALB/c mice were given subcutaneous injections of 5 mg/kg of bilirubin, 500 mg/kg of TUDCA, or corresponding vehicle 24 and 1 h before constant exposure to 5000 lux of white light for 8 h and then returned to a 12 h/12 h normal intensity light/dark cycle. Some mice were not exposed to constant light to serve as controls. Scotopic and photopic electroretinograms (ERGs) were done 1 and 7 days after light exposure. The bars show mean (± SEM) scotopic a-wave (a) and b-wave (b) amplitudes recorded after a flash intensity of 25 cd/s/m² and mean (± SEM) photopic b-wave amplitudes (c) recorded after a flash intensity of 25 cd/s/m² with a background light intensity of 30 cd/s/m².

Compared to their corresponding vehicle (HSA or NaHCO₃) controls, mice treated with bilirubin or TUDCA had significantly higher scotopic a-wave (a), scotopic b-wave (b), and photopic b-wave amplitudes at 1 and 7 days after light exposure. *p < 0.05 by unpaired Student’s t-test for difference between treated mice exposed to light toxicity and the respective vehicle-treated control exposed to light toxicity.
The ONL contains only the nuclei of rods and cones and therefore the thickness of the ONL provides an assessment of the number of photoreceptors at that location in the retina. As cones comprise only one row of nuclei and the remainder of the ONL is comprised of rods, thinning of the ONL is essentially an indication of rod cell death, but as the ONL thickness varies at different locations in the retina, comparisons between mice must be done at identical locations. Seven days after exposure to bright light (5000 lux) for 8 h, the mean ONL thickness was significantly greater in six different locations of the retina in mice treated every 3 days with 5 mg/kg of bilirubin or 500 mg/kg of TUDCA compared to mice treated with the corresponding vehicle (HSA or NaHCO₃) or untreated mice (Fig. 2a). Representative sections from the S1 location for each of the treatment groups is shown in Fig. 2(b) and illustrates that compared to retinas from the three different control groups, those from bilirubin- or TUDCA-treated mice showed thicker ONLs and better tissue preservation. BALB/c mice injected with 5 mg/kg of bilirubin or 500 mg/kg of TUDCA and not exposed to light (n = 4 for each) showed no difference in ONL thickness or appearance of the retina compared to untreated mice (data not shown). In light exposed mice, cone cell density was not significantly different in untreated, control mice compared to those treated with
bilirubin or TUDCA (n = 3 for each, data not shown), but untreated mice showed loss of cone outer segments and flattening of inner segments (Fig. 2c, left panel), while mice treated with bilirubin (middle panel) or TUDCA (right panel) showed preservation of cone inner and outer segments (arrows).

In the presence of superoxide radicals, hydroethidine is converted to ethidium which binds DNA and fluoresces. After i.p. injection of hydroethidine, there was no fluorescence in the retina of mice that were not exposed to bright light, but there was intense fluorescence in the photoreceptors of mice 7 days after exposure to bright light indicating the presence of many more superoxide radicals (Fig. 2d). The fluorescence was eliminated in light-exposed mice treated with bilirubin or TUDCA indicating effective scavenging of superoxide radicals.

**Treatment with bilirubin or TUDCA slows cone photoreceptor death in rd10+/+ mice**

In rd10+/+ mice, a missense mutation in exon 7 of the Pde6b gene results in rod photoreceptor cell death between P18 and P30 (Chang et al. 2002, 2007; Gargini et al. 2007). Once there is substantial reduction in the number of rods, cones and remaining rods undergo progressive oxidative damage, which accelerates the death of the remaining rods and causes cone cell death over several weeks (Komeima et al. 2007). Rd10+/+ mice were given subcutaneous injections of 5 mg/kg of bilirubin or 500 mg/kg of TUDCA every 3 days starting at postnatal day (P) 6. At P30, mean scotopic a- and b-wave amplitudes, and photopic b-wave amplitudes were significantly greater in mice that had been treated with bilirubin or TUDCA compared to mice treated with the corresponding vehicle (Fig. 3). At P50, scotopic ERGs were extinguished in all mice indicating complete loss of rod cell function (data not shown). Compared to untreated rd10+/+ mice, those treated with 5 mg/kg of bilirubin or 500 mg/kg of TUDCA every 3 days had greater preservation of cone cell function as indicated by mean low background [1.0 log (cds/m²)] photopic b-wave amplitudes that were 2- to 3-fold higher (Fig. 3b, p = 0.037; p = 0.029, respectively).

At P30, compared to untreated rd10+/+ mice, those treated with 5 mg/kg of bilirubin showed a significantly thicker ONL in four of six locations, and those treated with 500 mg/kg of TUDCA showed a significantly thicker ONL in three of six locations. At P50, retinal flat mounts stained with rhodamine-labeled peanut agglutinin, showed fairly well-preserved cone densities in rd10+/+ mice treated with 500 mg/kg of TUDCA, 5 mg/kg of bilirubin, or 50 mg/kg of bilirubin, compared to untreated mice (Fig. 4b). Image analysis confirmed that mice treated with TUDCA or either dose of bilirubin had significantly higher cone density in all four quadrants of the retina than untreated mice (Fig. 4c).

**Discussion**

There is substantial evidence indicating that bilirubin functions as part of the endogenous antioxidant defense system and elevated serum levels protect vascular endothelial cells from oxidative stress and reduce the risk of atherosclerosis (Ishizaka et al. 2001; Vitek et al. 2002; Djousse et al. 2003; Novotny and Vitek 2003). The effects in the nervous system are more complex. Increased serum bilirubin levels protect distinct populations of neurons from ischemia-reperfusion injury, but some neurons are susceptible to bilirubin-induced damage and elevation of serum bilirubin in infants, particularly when conditions do not favor albumin binding, can
cause permanent damage to the basal ganglia, a disease state called kernicterus (Ostrow et al. 2004; Wennberg et al. 2006). In this study, we have demonstrated that retinal photoreceptors, a highly specialized type of neuron, are protected against the damaging effects of excessive light stimulation by systemic injections of bilirubin with HSA. Excessive light stimulation increases levels of all-trans retinal which is highly reactive and readily generates ROS. Light damage can be reduced by directly targeting all-trans retinal (Maeda et al. 2009) or by providing antioxidants that scavenge the ROS that are generated (Li et al. 1985; Tanito et al. 2002). Bilirubin acts to reduce the number of superoxide radicals in light-exposed retinas. Injections of 5 or 50 mg/kg of bilirubin every 3 days significantly reduced cone cell death in the rd10+/+ model of RP as has been seen with other antioxidants (Komeima et al. 2006, 2007). Doses of bilirubin higher than 50 mg/kg caused hair loss and could not be continued, but did not cause evidence of retinal damage. Thus, increased serum levels of bilirubin protect rods and cones from oxidative damage.

Fig. 3 Bilirubin and TUDCA slowed the decline of photoreceptor function in rd10+/+ mice. Rd10+/+ mice were given subcutaneous injections of bilirubin (5 mg/kg) or its HSA vehicle, TUDCA (500 mg/kg) or its NaHCO3 vehicle, or no injection every 3 days starting at postnatal day (P) 6. Scotopic and photopic electroretinograms (ERGs) were performed at P30 and P50. The bars show mean (± SEM) ERG amplitudes. (a) At P30, scotopic a-wave amplitudes were significantly higher for bilirubin (n = 10) compared to its vehicle (n = 8) at the three highest stimulus intensities and TUDCA (n = 6) was significantly higher at the two highest stimulus intensities compared to its vehicle (n = 6). Scotopic b-wave amplitudes show a significant difference for bilirubin compared to its vehicle at the five highest stimulus intensities and TUDCA compared to its vehicle at two of the highest stimulus intensities. Photopic b-wave amplitudes at P30 show a significant difference for bilirubin compared to its vehicle at the two highest stimulus intensities and TUDCA compared to its vehicle at the highest stimulus intensity. There was no statistically significant difference between the bilirubin-treated mice and the TUDCA-treated mice at any stimulus intensity. There was no significant difference between any of the three control groups (HSA, NaHCO3, and no injection) at any stimulus intensity. *p < 0.05 by unpaired Student’s t-Test for difference between treated mice and their respective vehicle-treated control group. (b) Photopic b-wave ERGs with low background light (10 cd s/m²) at P50 show a significant difference for rd10+/+ mice injected with either bilirubin (n = 8), or TUDCA (n = 6), compared to rd10+/+ control mice (n = 4) that received no injection. Representative wave forms are shown (inset) for the non-injected, bilirubin-treated, and TUDCA-treated rd10+/+ mice. There was no significant difference between the HSA or NaHCO3 vehicle-treated rd10+/+ mice compared to the rd10+/+ mice that received no injection. *p < 0.05 for difference from untreated control by ANOVA with Bonferroni correction for multiple comparisons.
Tauroursodeoxycholic acid is another constituent of bile that has previously been shown to provide benefit from excessive light exposure in models of RP (Boatright et al. 2006; Phillips et al. 2008). We have confirmed those findings and have demonstrated that TUDCA acts by reducing oxidative stress. Although high doses of TUDCA are required, the effects are similar to those seen with bilirubin. For both bilirubin and TUDCA, the predominant effect in rd10+/+ mice is to preserve cone cell function and structure; the effect on rod survival is modest and transient. This is consistent with effects of other antioxidants (Komeima et al. 2007; Usui et al. 2009a) and suggests that other mechanisms in addition to oxidative stress play a major role in rod cell death in rd10 mice, but it is a major factor leading to the demise of cones.

The antioxidant-induced reduction of cone cell death in models of RP suggests that an optimized antioxidant formulation could provide benefit in patients with RP and a clinical trial should be considered. However, design of such a trial is difficult because of variable rates of progression among RP patients, even those with the same mutation, presumably because of differences in genetic background and environmental exposures. Considering the variability and the relatively slow rate of progression in most patients, a very large study with a 2- or 3-year endpoint would be required to have a chance of identifying a treatment benefit. However, our findings suggest an alternative strategy to test the hypothesis that cones die from oxidative damage in patients with RP before embarking on an expensive and long interventional trial. Approximately 3–17% of the population (depending upon ethnicity) have Gilbert’s syndrome in which there is modest elevation of serum bilirubin because of a mutation in the promoter region of uridine diphosphate glucuronosyltransferase the gene product of which is involved in conjugation of bilirubin facilitating its excretion from the body (Fertrin et al. 2002). Bilirubin in serum is non-covalently bound to HSA which functions as its physiologic carrier, analogous to our experimental paradigm in which HSA was given in combination with albumin. Patients with Gilbert’s syndrome show protection against diseases in which oxidative stress is involved (Vitek et al. 2002; Novotny and Vitek 2003; Bulmer et al. 2008; Schwertner and Vitek 2008). As it is a relatively common condition, it may be possible to determine if patients with RP...
and Gilbert’s syndrome have slower disease progression than a cohort of RP patients that are similar but have normal serum bilirubin levels. If there is an inverse correlation between serum bilirubin levels and progression of disease in patients with RP, this would increase motivation for an interventional trial, and provide an important baseline feature that should be stratified. The implications regarding the findings with TUDCA are also important. It is inexpensive, well tolerated, and may have a similar safety profile as the United States Food and Drug Administration approved nontaurine-conjugated analog UDCA. Therefore, TUDCA is a good candidate for inclusion in an antioxidant test regimen.
